Key words: H4IIE liver cells, patch-clamp recording, iso-tetrandrine, CRAC channels

Abbreviations: SOCs – store-operated Ca\(^{2+}\) channels; AA– arachidonic acid; \([Ca^{2+}]_{cyt}\) – Ca\(^{2+}\) concentration in cytoplasmic space
SYNOPSIS
Vasopressin and other phospholipase C-coupled hormones induce oscillations (waves) of cytoplasmic $\text{Ca}^{2+}$ concentration ([Ca$^{2+}$]$_\text{cyt}$) in liver cells. Maintenance of these oscillations requires replenishment of Ca$^{2+}$ in intracellular stores through Ca$^{2+}$ inflow across the plasma membrane. While this may be achieved by store-operated Ca$^{2+}$ channels (SOCs), some studies in other cell types indicate that it is dependent on arachidonic acid (AA)-activated Ca$^{2+}$ channels. We studied the effects of AA on membrane conductance of rat liver cells using whole cell patch clamping. We found no evidence that concentrations of AA in the physiological range could activate Ca$^{2+}$-permeable channels in either H4IIE liver cells or rat hepatocytes. However, AA (1-10 µM) did inhibit (IC$_{50}$ = 2.4 ± 0.1 µM) Ca$^{2+}$ inflow through SOCs (I$_{\text{SOC}}$) initiated by intracellular application of inositol 1,4,5-trisphosphate in H4IIE cells. Pre-incubation with AA did not inhibit I$_{\text{SOC}}$ development, but decreased maximal amplitude of the current. Iso-tetrandrine, widely used to inhibit receptor-activation of phospholipase A$_2$, and therefore AA release, directly inhibited I$_{\text{SOC}}$ in H4IIE cells. It is concluded that, (i) in rat liver cells, AA does not activate an AA-regulated Ca$^{2+}$-permeable channel but does inhibit SOCs and (ii) iso-tetrandrine and tetrandrine are effective blockers of Ca$^{2+}$ release-activated Ca$^{2+}$ channel (CRAC)-like SOCs. These results indicate that AA-activated Ca$^{2+}$ permeable channels do not contribute to hormone-induced increases or oscillations in [Ca$^{2+}$]$_\text{cyt}$ in liver cells. However, AA may be a physiological modulator of Ca$^{2+}$ inflow in these cells.
INTRODUCTION

In non-excitable cells agonists acting at phospholipase C-coupled receptors generate repetitive rises in free Ca\(^{2+}\) concentration in the cytoplasmic space ([Ca\(^{2+}\)\(_{cyt}\)] by releasing Ca\(^{2+}\) from intracellular Ca\(^{2+}\) stores and activating Ca\(^{2+}\) influx through plasma membrane Ca\(^{2+}\) channels. It has been generally accepted that the major component of the receptor-activated Ca\(^{2+}\) entry into the cell is produced by a store-operated Ca\(^{2+}\) entry mechanism, which involves activation of store-operated Ca\(^{2+}\) channels (SOCs) in response to emptying intracellular Ca\(^{2+}\) stores by inositol 1,4,5-trisphosphate (IP\(_3\)) [1]. At the same time a significant body of evidence suggests that a non-store-operated Ca\(^{2+}\) entry may also be activated by phospholipase-C coupled receptors [2-4]. In A7r5 vascular smooth muscle cells, avian nasal gland cells, and HEK293 cells stably transfected with human m3 muscarinic receptor (m3HEK293 cells) non-store-operated Ca\(^{2+}\) influx stimulated by arachidonic acid (AA) has been suggested to be a major pathway for Ca\(^{2+}\) entry activated by physiological concentrations of specific agonists that induce intracellular Ca\(^{2+}\) waves [5-7].

AA, a cis-polyunsaturated fatty acid, is a constituent of membrane phospholipids that can be released by cellular phospholipases, particularly by phospholipase A\(_2\) and diacylglycerol lipase [8]. Free AA has been shown to modulate the activity of a number of ion channels including a range of Ca\(^{2+}\) permeable channels [9-11]. There is no single mechanism of action by which AA modulates ion channels. Thus there is evidence that it directly binds to some channel proteins, but for other channels can also have an indirect effect through its metabolites, free radicals, and AA-sensitive protein kinases and phosphatases [12-14]. In some cells in which AA has been shown to inhibit SOCs, it has also been shown to activate a specific Ca\(^{2+}\) conductance [15]. Patch-clamping of m3HEK293 cells revealed that, in these cells, AA activates a Ca\(^{2+}\) current (I\(_{ARC}\)) that is distinctively different from that activated by store depletion (I\(_{SOC}\)) [16]. This current was implicated in mediating Ca\(^{2+}\) oscillations activated by low concentrations of carbachol in these cells [17].

Hepatocytes are polarised epithelial cells in which Ca\(^{2+}\) oscillations can be activated by a variety of Ca\(^{2+}\) mobilising hormones. They exhibit a Ca\(^{2+}\) selective current mediated by SOCs (I\(_{SOC}\)) that has been characterised by patch clamp recording [18, 19]. The hepatocyte I\(_{SOC}\) exhibits many of the characteristics, including high Ca\(^{2+}\) selectivity, of I\(_{CRAC}\) studied in lymphocytes and mast cells [18, 19]. Indirect evidence indicates that hormone-induced Ca\(^{2+}\) oscillations in hepatocytes are maintained by store-operated Ca\(^{2+}\) entry mechanism, as they are inhibited by known blockers of SOCs [19]. On the other hand, there is evidence that Ca\(^{2+}\) mobilising hormones induce AA release [20].
The present work was designed to elucidate the effects of AA on SOCs in liver cells, and to establish whether AA activates a specific Ca\(^{2+}\) conductance in these cells. The results indicate that AA, at concentrations within the estimated physiological range, inhibits I\(_{SOC}\) in rat liver H4IIE cells, but does not itself activate any type of membrane conductance in either H4IIE cells or in rat hepatocytes. We also show that iso-tetrandrine, commonly used to inhibit activation of phospholipase A\(_2\) by receptors and therefore AA release [21], is a potent blocker of the I\(_{SOC}\) in H4IIE cells.

**EXPERIMENTAL**

**Cell culture**

H4IIE cells (ATCC CRL 1548) were cultured at 37°C in 5% (v/v) CO\(_2\) in air in Dulbecco’s modified Eagle’s medium (DMEM, Gibco) supplemented with penicillin (100 units/ml), streptomycin (100 µg/ml), 10 mM HEPES (pH 7.4) and 10% (v/v) foetal bovine serum (complete DMEM) [22]. The cells were subcultured for a maximum of 15 passages. Hepatocytes were isolated from male Hooded Wistar rats by liver perfusion with collagenase, plated on glass cover slips in complete DMEM (as above) and used for patch clamping on the following day [23].

**Electrophysiology**

Whole-cell patch clamping was performed at room temperature using a computer-based patch-clamp amplifier (EPC-9, HEKA Electronics, Germany) and PULSE software (HEKA Electronics). The usual bath solution contained (mM): NaCl, 140; CsCl, 4; CaCl\(_2\), 10; MgCl\(_2\), 2; Glucose 10; and HEPES, 10; adjusted to pH 7.4 with NaOH. The internal solution 1 contained (mM): Cs glutamate, 120; CaCl\(_2\) 5; MgCl\(_2\) 5; MgATP 1; EGTA, 10; and HEPES, 10; adjusted to pH 7.2 with NaOH. The internal solution 2 contained: Cs glutamate, 130; CsCl, 10; CaCl\(_2\) 0.5; MgATP 6; EGTA, 1; and HEPES, 10; adjusted to pH 7.2 with NaOH. The calculated internal free Ca\(^{2+}\) concentration for each internal solution was about 100 nM (EQCAL, Biosoft, Cambridge, UK). Depletion of the intracellular Ca\(^{2+}\) stores was achieved by addition of 20 µM IP\(_3\) (D-myo-Inositol 1,4,5-trisphosphate hexapotassium salt, Sigma) to internal solution 1 or 1 µM thapsigargin (Sigma) to the bath solution. Patch pipettes were pulled from borosilicate glass, coated with Sylgard and fire-polished; pipette resistance ranged between 2-4 MΩ. In order to monitor the development of I\(_{SOC}\), voltage ramps between –138 and +102 mV were applied every 2 s, starting immediately after achieving the whole-cell...
configuration. Acquired currents were filtered at 2.7 kHz and sampled at 10 kHz. Traces presented in the figures were further digitally filtered at 1.5 kHz. All voltages shown have been corrected for the liquid junction potential of -18 mV between the bath and electrode solutions (estimated by JPCalc [24]). The holding potential was -18 mV throughout. Cell capacitance was compensated automatically by the EPC9 amplifier. AA and tetrandrine were purchased from Sigma; iso-tetrandrine was purchased from Calbiochem.

RESULTS

First, the effect of AA on the membrane conductance of H4IIE rat liver cells was investigated to establish if AA activates a specific Ca\(^{2+}\) current. As it has been recently suggested that pre-activation of capacitative Ca\(^{2+}\) entry may inhibit AA-induced Ca\(^{2+}\) entry [15], in these experiments we used an intracellular solution containing 6 mM Mg ATP and Ca\(^{2+}\) buffered to 100 nM with 1 mM EGTA. This would prevent the spontaneous development of I\(_{\text{SOC}}\) and would also minimize the contribution of Mg\(^{2+}\) regulated non-selective cation current attributed to TRPM7 [25]. Addition of 10 \(\mu\)M AA to the bath solution under these conditions failed to activate any current within 10 minutes of recording (Fig. 1A).

H4IIE cells are likely to have lost receptors normally present in rat hepatocytes, as they do not respond to ATP (up to 100 \(\mu\)M) or vasopressin (authors unpublished observations). It might be argued that AA-activated Ca\(^{2+}\) entry requires the presence of functional G-protein coupled receptors on the plasma membrane, or that AA-activated Ca\(^{2+}\) channels themselves have been lost in this particular cell line. Therefore similar experiments were performed on rat hepatocytes in primary culture that are known to generate cytoplasmic Ca\(^{2+}\) waves in response to a variety of hormones [19, 26, 27]. AA (up to 20 \(\mu\)M) in the bath solution failed to activate any current in rat hepatocytes within 10 minutes of recording (Fig. 1B), indicating that the failure to observe any AA-activated current in H4IIE cells is unlikely to be due to the loss of expression of G-protein-coupled receptors, and that the absence of AA-activated channels is not unique to H4IIE cells.

The fact that AA does not activate Ca\(^{2+}\) conductance in liver cells does not imply that it has no role in Ca\(^{2+}\) signalling in these cells. AA has been shown to inhibit store-operated Ca\(^{2+}\) entry in various cell types [15, 28-30]. However, its effects on SOCs in liver cells and on similar CRAC-type SOCs in other cell lines are not known. Therefore, in the next set of experiments we investigated the effect of AA on I\(_{\text{SOC}}\) in H4IIE cells. We have previously characterised I\(_{\text{SOC}}\) in H4IIE cells and shown that it has many of the properties of I\(_{\text{CRAC}}\) in...
lymphocytes and mast cells [18]. In the absence of AA, depletion of intracellular Ca\(^{2+}\) stores in H4IIE cells activated an inward current (I\(_{\text{SOC}}\)) with a magnitude of about -2.5 pA/pF, measured at -118 mV, as described previously [18] (Fig 2A). The current reached its maximum within 60 s after achieving the whole-cell configuration with the pipette containing 20 µM IP\(_3\) and then slowly decayed to a level of 60-70% of the maximal amplitude. Addition of 10 µM AA to the bath solution after full development of the current produced almost complete block of I\(_{\text{SOC}}\) within 150 s. At lower concentrations the block was slower in onset and less complete. The lowest concentration of AA that produced a significant effect within 200 s of application was 1 µM (Fig.2A). Higher concentrations of AA (20-50 µM) blocked I\(_{\text{SOC}}\) faster, however, they frequently caused development of a non-specific leakage and electrical breakdown of the membrane during steps to negative potentials (not shown). The apparent half-maximal inhibitory concentration for AA measured 200 s after AA application was 2.4±0.1 µM (n=4) (Fig.2B).

Pre-incubation of H4IIE cells with 10 µM AA in the bath for at least two minutes before achieving whole-cell configuration did not prevent development of I\(_{\text{SOC}}\) (Fig. 2C). However, the maximal amplitude of the current was significantly smaller and it was completely inactivated within 200 s of recording. The time constants of I\(_{\text{SOC}}\) development were 24±2 s (n=6) for the control cells and 20±3 s (n=6) for the cells pre-incubated with AA. These results indicate that it is unlikely that AA interferes with the mechanism of I\(_{\text{SOC}}\) activation, or that it inhibits I\(_{\text{SOC}}\) by binding to the closed channel. It is more likely that AA either directly inhibits the open channel or modulates the mechanism by which I\(_{\text{SOC}}\) is slowly inactivated [31]. Addition of 10 µM of AA to the internal solution containing 20 µM IP\(_3\) had no effect on the development or amplitude of I\(_{\text{SOC}}\) (Fig 2C).

Under conditions used in the experiments with H4IIE cells described above (Fig. 1), AA did not seem to activate any specific conductance. However, in other cell types AA has been shown to activate highly selective Ca\(^{2+}\) channels with properties distinct from that of the SOCs in those cells [16]. One of the main differences between I\(_{\text{SOC}}\) and the current activated by AA (I\(_{\text{ARC}}\)) in HEK293 cells is the lack of the fast inactivation in the latter [16]. I\(_{\text{SOC}}\) in H4IIE cells also shows a significant fast Ca\(^{2+}\) dependent inactivation at negative potentials [32] and therefore can be easily distinguished from a current that shows no fast inactivation. While there was no evidence that AA activated any current in H4IIE cells, the possibility of a transient activation of such a current when I\(_{\text{SOC}}\) is blocked could not be excluded. Therefore we compared current traces obtained in response to -138 mV voltage steps before, and 60 s
after, application of AA. The kinetics of the $I_{SOC}$ inactivation and the relative amplitude of the non-inactivating component at negative potentials remained unaffected in the presence of AA (Fig 3A, B). This argues against the presence of any non-inactivating $Ca^{2+}$ current additional to $I_{SOC}$. Moreover, the I-V plot remained inwardly rectifying in the presence of AA with no evidence for the development of any outward current or a shift in the reversal potential (which would be expected if any other conductance had developed) (Fig. 3C).

One of the methods of distinguishing between $Ca^{2+}$ influxes carried by $I_{SOC}$ and $I_{ARC}$ in m3HEK293 cells, where $I_{ARC}$ was first described, was to use iso-tetrandrine. Iso-tetrandrine is known to inhibit the activation of phospholipase A$_2$ by receptors [21], and therefore has been used to inhibit agonist-induced AA release [6, 15]. Iso-tetrandrine is also one of the stereoisomers of tetrandrine that blocks L-type and T-type $Ca^{2+}$ channels [33]. The effects of either compound on store-operated $Ca^{2+}$ entry have not been previously investigated in most cell types. However, in avian nasal gland cells iso-tetrandrine had no effect on thapsigargin-activated $Ca^{2+}$ inflow [6]. In H4IIE cells both tetrandrine and iso-tetrandrine caused a dose dependent inhibition of $I_{SOC}$ (Fig.4, only tetrandrine is shown). The apparent half-maximal inhibitory concentration for tetrandrine was $8.6\pm0.3$ µM (n= 4-12) (Fig.4B). At concentrations of 10 and 100 µM, iso-tetrandrine showed potency similar to that of tetrandrine in inhibiting $I_{SOC}$ (not shown). The onset of the block induced by tetrandrine and iso-tetrandrine was as rapid as that observed with La$^{3+}$ (authors, unpublished) and was easily reversible upon washout (not shown). Both tetrandrine and iso-tetrandrine had the same effect when $I_{SOC}$ was activated by either thapsigargin or IP$_3$.

**DISCUSSION**

The existence of AA activated $Ca^{2+}$ entry has been shown in a variety of cell types [5, 6, 34, 35]. In some of these cell types, AA activated $Ca^{2+}$ channels provide a major pathway for $Ca^{2+}$ entry during $Ca^{2+}$ oscillations triggered by receptor stimulation [5, 17, 29]. In contrast, in astrocytes AA inhibits $Ca^{2+}$ oscillation activated by ATP and activates sustained $Ca^{2+}$ influx [30]. The results of the present study demonstrate that AA, in the predicted physiological range of concentrations [36], does not activate $Ca^{2+}$-permeable channels in H4IIE liver cells, but strongly inhibits $Ca^{2+}$ entry through SOCs (cf [15, 28-30]). The observation that AA also did not activate $Ca^{2+}$ permeable channel in primary rat hepatocytes indicates that the failure to observe an AA-activated current in H4IIE liver cells is unlikely to be due to the absence of receptors for agonists in this immortalised cell line.
These results imply that, unlike some other cell types including vascular smooth muscle cells and m3HEK293 cells, liver cells do not rely on AA-activated Ca\(^{2+}\) entry to maintain Ca\(^{2+}\) oscillations generated in response to phospholipase C-coupled hormones. Moreover, the idea that SOCs are responsible for Ca\(^{2+}\) inflow that maintains Ca\(^{2+}\) oscillations in liver cells [19] is consistent with the present observations of the absence of an AA-activated Ca\(^{2+}\) permeable channels in liver cells.

The observation that the intracellular application of AA had no effect on I\(_{\text{SOC}}\) development and amplitude suggests an extracellular or membrane-delimited site of action for AA. However, an intracellular site cannot be unequivocally ruled out as application of a membrane-permeable substance like AA through a patch pipette may not be as effective in maintaining the exogenous AA concentration since the AA will diffuse into the infinitely large (compared to the cell volume) bath faster than it diffuses through a patch pipette. AA may also be metabolised faster than it is incorporated into the plasma membrane, if the site of action is membrane-delimited. This appears to be the case in studies of the regulation of I\(_{\text{CRAC}}\) by sphingosine, another membrane-permeable compound. Sphingosine that accumulates in the membrane, as assessed by the changes in the membrane capacitance, and inhibits I\(_{\text{CRAC}}\) in RBL cells when applied in the bath has no effect on either capacitance or I\(_{\text{CRAC}}\) when applied through the pipette [37]. Regardless of the site of action in liver cells AA may be an important modulator of Ca\(^{2+}\) entry through SOCs when these are activated by physiological concentrations of hormones that induce the formation of AA. Under physiological conditions AA is produced in the membrane [8], and in vivo when cells are packed close to each other in an intact organ, concentration of AA acid is likely to rise both inside and outside of the cells.

In m3HEK293 cells, Ca\(^{2+}\) currents activated by AA and depletion of Ca\(^{2+}\) stores were additive [16]. Thus, addition of AA after I\(_{\text{SOC}}\) development in m3HEK293 cells increased membrane current further. By contrast, in the present studies with H4IIE cells, I\(_{\text{SOC}}\) was completely inhibited by similar concentrations of AA. This suggests that I\(_{\text{SOC}}\) in HEK cells and I\(_{\text{SOC}}\) in H4IIE cells are likely to be mediated by different types of SOCs. Moreover, these results emphasise that conclusions about the nature of Ca\(^{2+}\) permeable pathways in the plasma membrane for one cell type cannot necessarily be applied to another cell type.

Another important observation of this study is that iso-tetrandrine and tetrandrine are potent inhibitors of I\(_{\text{SOC}}\) in liver cells. The mechanism of inhibition is unlikely to involve an effect of these agents on phospholipase A\(_2\) as the block is very rapid and readily reversible. A direct effect of tetrandrine and iso-tetrandrine on the SOC is consistent with these observations. In addition, if iso-tetrandrine and tetrandrine were acting via phospholipase A\(_2\),
they would be expected to enhance $I_{SOC}$, not to inhibit it, since the present results show that AA, a product of phospholipase A$\textsubscript{2}$ activity, inhibits SOCs in liver cells. In avian nasal gland cells, iso-tetrandrine has been shown to inhibit $\text{Ca}^{2+}$ oscillations activated by a low concentration (0.5 µM) of carbachol, but was found ineffective in inhibiting $\text{Ca}^{2+}$ entry activated by a high concentration (10 µM) of carbachol or by thapsigargin [6]. It was concluded from these experiments that in avian nasal gland cells, iso-tetrandrine does not affect SOCs, that SOCs are not activated by low concentrations of carbachol and, therefore, that the major physiological pathway for $\text{Ca}^{2+}$ entry in these cells is through $\text{Ca}^{2+}$ channels activated by AA. In view of the present studies, caution should be exercised in interpretation of the results obtained using these compounds as inhibitors of receptor-activation of phospholipase A$\textsubscript{2}$ in studies involving the measurement of SOCs, especially when employing $\text{Ca}^{2+}$ florescent dyes to measure $\text{Ca}^{2+}$ inflow, and when the nature of the channels underlying that inflow is not entirely certain.

The observations made by several research groups with different cell types on the effects of AA on plasma membrane $\text{Ca}^{2+}$ permeable channels can be summarised as follows. In different cell types AA has been shown either to induce $\text{Ca}^{2+}$ oscillations [6], or to inhibit them [30]; to inhibit SOC-mediated $\text{Ca}^{2+}$ entry [15, 28-30], or to have no effect on SOCs [16]; to activate $\text{Ca}^{2+}$ channels with a high selectivity for $\text{Ca}^{2+}$ [16], or to activate $\text{Ca}^{2+}$ permeable non-selective cation channels [38]; and to activate $\text{Ca}^{2+}$ permeable channels which are very sensitive to inhibition by Gd$^{3+}$ [34], or channels which are insensitive to Gd$^{3+}$ [5, 39, 40]. On the basis of all these results, it can be suggested that AA plays different physiological roles in regulating $\text{Ca}^{2+}$ entry, and may activate or inhibit different types of $\text{Ca}^{2+}$-permeable channels in different cell types. The results also indicate that SOCs are likely to be different in different cell types and no single model of the mechanism of $\text{Ca}^{2+}$ oscillations can be applied to all cell types.
